The interaction of an electron beam with chalcogenide films $\text{As}_4\text{Se}_{96}$ has been studied. The kinetics of the formation of an electron-induced surface relief in the dose range $9.3 \times 10^3$–$9.3 \times 10^7 \mu \text{C} \cdot \text{cm}^{-2}$ is established. The parameters of the interaction of a film $\text{As}_4\text{Se}_{96}$ with an electron beam are calculated. It is shown that the observed point of inversion of the shape of the electron-induced relief can be caused by the crossover of the surface potential. The process of manufacturing the image element by the single-step lithography is realized on the surface of an $\text{As}_4\text{Se}_{96}$ film.

**Keywords:** chalcogenide glass, thin films, As–Se, electron-induced surface relief.

---

**1. Introduction**

Chalcogenide films exhibit the sensitivity to light irradiation which has been exploited in the production of functional devices for microelectronics, integrated optics, and holograms. The mechanism of photoinduced processes involves the photogeneration and the interaction of charges, which lead to various structural changes. The intense generation of charges within a chalcogenide film occurs also under the electron irradiation. Investigations of the interaction of electron beams with chalcogenide films of the binary compositions As-Se [1], Ge-Se [2], and Sb-Se [3] have shown the formation of surface reliefs of various types depending on the charge deposited in a film. The recent studies of ternary chalcogenide systems based on Ge–As–Se have revealed unique electron-induced effects such as the electro-hydrodynamic instability [4] or inversion of the shape of an electron-induced surface relief [5,6].

The binary As–Se systems have a very high sensitivity to the irradiation. As shown in Ref. [7], a change in the direction of the lateral mass transport can be observed in the $\text{As}_x\text{Se}_{100-x}$ films with $x = 4.5$ during the formation of a photoinduced surface relief. The change occurs specifically in the low As concentration range (critical concentration $x = 4$ at.% As) and is caused by a topological transition of the $\text{As}_x\text{Se}_{100-x}$ glass structure from a one-dimensional annular structure to a one-dimensional chain one. When $2 < x < 6$ at.% As, the zero hole mobility is observed [8].

Electron beam-induced phenomena are related to the charge dissipation which can involve the charge transport by both electrons and holes. Taking the above-mentioned facts into account, we have chosen the $\text{As}_4\text{Se}_{96}$ system. This system exhibits also the extremely high sensitivity to the action of an electron beam, so we studied a possibility of using this
material for the high-speed fabrication of protective elements by the one-stage (dry) lithography. In this work, we will carefully determine the interaction with an electron beam in the range of radiation doses from $3 \times 10^3$ to $9.3 \times 10^7 \mu C \cdot cm^{-2}$.

2. Experimental Details

For this study, the amorphous films of As$_x$Se$_{96}$ with a thickness of 4 μm were prepared. These films were obtained by the thermal evaporation in vacuum using a glass of the same chemical composition. The films were deposited on sapphire substrates at a rate of 10 nm/s. Freshly prepared films were used in the measurements.

The films were irradiated with electrons using a scanning electron microscope (SEM) Tescan, model VEGA. The following parameters were used: the accelerating voltage $V = 30$ kV, spot size $B = 0.64$ μm, and electron beam current $I = 60$ nA. The irradiation dose was determined by the formula $G = I \times t / S$, where $S$ is the cross-section area of an electron beam focused on the film surface; $t$ is the time of irradiation. The exposure times were changed from 0.05 ms to 5 s, the time dependence of the exposure dose was calculated by the formula $G = 18.6 \times 10^6 \times t$ (μC·cm$^{-2}$). To facilitate the surface charge removal, the irradiation of the films was carried out in a low-vacuum atmosphere of nitrogen at a residual pressure of 10 Pa. The structure of the induced surface reliefs on the film surface was studied using an atomic force microscope (AFM) (Bruker, ICON model) in the “tapping mode”.

3. Results of Experiments

The irradiation of films was carried out during the exposure times from 0.05 ms to 5 s, which determined doses in the range from $9.3 \times 10^2$ to $9.3 \times 10^7$ μC·cm$^{-2}$. For each individual dose $G$, a square matrix (20×20) of point-irradiated regions was made on the surface of the film. The matrix period $d$ was 10 μm. The value of $d$ was chosen large enough to avoid the proximity effects [9]. To study the surface relief in the irradiated regions, the surface was scanned by AFM. Figure 1 shows the AFM scans of the irradiated regions of As$_x$Se$_{96}$ films and the profiles of the electron beam-induced surface reliefs. From Fig. 2, it can be seen that the kinetics of surface relief formation for As$_x$Se$_{96}$ films in the range from $9.3 \times 10^2$ to $9.3 \times 10^7$ μC·cm$^{-2}$ is characterized by three ranges of radiation doses in which reliefs of different shapes are formed

- Below $G < 1.2$ μC·cm$^{-2}$ ($t < 65$ μs), the cones with a Gaussian profile are formed;
- $1.2$ μC·cm$^{-2} < G < 46.5$ μC·cm$^{-2}$ ($65$ μs $< t < 2.5$ ms) – the dose range in which the height of cones of the Gaussian type remains practically unchanged;
- $46.5$ μC·cm$^{-2} < G < 9.3 \times 10^4$ μC·cm$^{-2}$ ($2.5$ ms $< t < 5$ s) is the range of doses in which craters of the same type are formed with depth $h_2$.

Ranges 2 and 3 are separated by the inversion point [10] – the irradiation dose $G_1$ at which the shape of the surface relief changes – from a cone to a crater.

In Fig. 2, the dependences of the surface relief parameters $h$, $S$, and $d$ on the irradiation time are given, where: $h$ is the height (depth), $S$ is the cross-section area, and $d$ is the half-width of the surface cone (crater). It can be seen from Fig. 2 that these parameters of the surface relief of films depend on the irradiation time. When constructing their time dependences in the coordinates $lg t$ on the graphs, rectilinear sections are observed.

In particular, an increase in $h_1$ occurs with increasing $t$ in the interval 40–65 μs. The linear approximation of the dependence of $h(t)$ on the value $h = 0$ indicates that the maximum irradiation time ($G_0 \approx 0 \mu C \cdot cm^{-2}$). In the interval 65±80 μs, the value of $h(t)$ remains almost unchanged. At $t > 80$ μs, the value of $h_1$ decreases, and, subsequently, the cone turns into a crater whose depth $h_2$ increases with $t$.

With an increase in $t$ in the interval 80 μs $< t < 5$ s, the dependence $h(t)$ can be approximated by a decreasing straight line in the coordinates “$h$-lg $t$”. The intersection of this line with the abscissa axis gives the inversion point at $t = 2.5$ ms (inverse dose $G_0 = 46.5 \times 10^3$ μC·cm$^{-2}$).

The changes in $S$ and $d$ during the irradiation on a logarithmic scale have a linear dependence in individual intervals. In particular, in the interval 0.04 μs $< t < 1$ ms, the cross-section area of the cones increases linearly. Further, as the irradiation time increases to the inversion point, $S$ decreases. Later on, at the irradiation, craters with increasing parameters $h_2$ and $S$ are formed.

Interaction of Chalcogenide As$_4$Se$_96$ Films with Electron Beam

The diameter of the relief of the irradiated region $d$ in the “$d$–$\lg t$” coordinates increases linearly in the interval $0.04 \text{ ms} < t < 50 \text{ ms}$. Subsequently, with increasing $t$, the parameter $d$ is not changed.

4. Discussion

The kinetics of formation of a surface relief and changes in its shape and parameters during the electron irradiation of the As$_4$Se$_96$ film can be explained using the charge model which was used earlier for Ge–As–Se films [6]. The mechanism of formation of various types of a surface relief in this model is the electrostatic interaction in the space charge region caused by the formation of two dynamically changing charged layers which are induced in the chalcogenide film during its electron irradiation.

It is known that when the electron beam hits the film surface, various physical phenomena related to the transmission of the energy of electrons to the exposed material in the irradiated region occur. The transfer of the energy of electrons occurs during their inelastic collision with atoms of the film being studied in the region of their interaction. The $R$ value of the interaction region for the As$_4$Se$_96$ film was calculated by the Kanaya–Okayama formula [11]:

$$R = 0.0276 \frac{A E_0^\frac{3}{2}}{\rho Z^\frac{5}{2}},$$

where $A$ is the average atomic weight, $Z$ is the average charge of the nucleus, $\rho$ is the density of the irradiated substance, $E_0$ is the energy of primary electrons.

When calculating the parameter $R$ for the As$_4$Se$_96$ film, the following numerical values were taken: $A = 78.84 \text{ (g/mol)}$, $Z = 33.96$, $\rho = 4.33 \text{ g/cm}^3$, $E_0 = 30 \text{ keV}$. The average atomic weight $A$ and the av-
Fig. 2. Changes of the parameters of the electron-induced surface relief of an As$_4$Se$_9$ film depending on the irradiation time: height – the height of the cones, depth – the depth of the craters, area – the axial section area, $d$ – the half-width

average nuclear charge $Z$ were determined by the formulas: $A = c_1 A_1 + c_2 A_2$ and $Z = c_1 Z_1 + c_2 Z_2$, where $c_1 = 0.04$, $c_2 = 0.96$, – As and Se concentrations, and $A_1$, $A_2$, and $Z_1$, $Z_2$ are their atomic weights and nuclear charges, respectively. As a result of this calculation, the value $R \approx 6.3 \mu m$ was obtained.

The shape of the interaction region depends on the average nucleus charge $Z$ of atoms of the substance, electron energy, and angle of incidence of a beam. In our case, the shape of the interaction region is close to a spherical surface with a transverse dimension of $6.3 \mu m$ [12]. In this region, under the electron irradiation influence, a space charge region is formed and causes the formation of a surface relief in the chalcogenide film.

The mechanism of charging the film involves the competition between the number of incident electrons which penetrate into the film and generate charges along their movement trajectory and the numbers of ejected secondary and backscattered electrons from the sample to vacuum.

When the electron irradiation penetrates the As$_4$Se$_9$ film, electrons and holes are generated by primary electrons. The scattered energy of incident electrons partially goes to the formation of non-equilibrium electron-hole pairs, causing a substantial increase in the number of mobile charge carriers. The average energy of formation of an electron-hole pair for As$_4$Se$_9$ (2 ≈ eV [13]) is much smaller than the energy of the incident electron. Therefore, one electron with an energy of 30 keV along its trajectory in a chalcogenide film can create several thousand electron-hole pairs.

As a result of the penetration of primary electrons into the film and their capture at deep and shallow energy levels, a negative charge $Q_-$ is formed in the film. Its thickness is equal to the penetration depth of incident electrons into the sample. Due to the emission of secondary electrons from the near-surface layers of the film back into vacuum, a relatively thin near-surface layer with positive charge $Q_+$ is formed. In other words, at the electronic irradiation, the charge accumulates in the volume and on the film surface. These two layers of charges ($Q_-$ and $Q_+$) create an electric field in the region of interaction of the film and the electron beam [14]. As a consequence, a potential $V_s$ appears on the film surface, and its magnitude and sign depend on the total charge $\Delta Q = |Q_- - Q_+|$ [15]:

$$V_s = \frac{\Delta Q h}{\varepsilon_0 \varepsilon_r S} + \frac{(Q_+ l + Q_- R)}{2 \varepsilon_0 \varepsilon_r S},$$  (2)

where $S$ is the area of the irradiated region, $h$ is the film thickness, $\varepsilon_0$ and $\varepsilon_r$ are the dielectric constant of vacuum and the material, respectively.

The appearance and magnitude of the charges $Q_+$ and $Q_-$ determine the shape and parameters of the surface relief of the film as a result of its expansion or contraction during the electrostatic interaction in the irradiated region.

It is known that a positive charge is formed in non-conducting materials in the near-surface region under the electron irradiation [16]. It can be assumed that the formation of a charge $Q_+$ in the near-surface layer of the As$_4$Se$_9$ film at the irradiation leads to the film expansion (due to the electrostatic repul-
sion. The height of the surface relief in the form of a cone increases with the irradiation time up to 65 μs (Fig. 2). Taking the electron emission coefficient $\sigma$ into account, the accumulated positive charge can be determined by the formula $Q_+ = \sigma I_0 t_+ = (\eta + \delta) I_0 t_+$, where $\sigma$ is the electron emission coefficient, $I_0 = 60$ nA is the electron beam current, $\delta$ and $\eta$ are the coefficients of secondary and backscattered electrons, respectively, $t_+$ is the rise time of a surface relief of the film (cone) at the initial stage of irradiation ($t_+ = 65$ μs). The reflection coefficient $\eta$ of the investigated chalcogenide film can be calculated from the formula [17]:

$$\eta(Z, E_0) = CE_0^m,$$

(3)

where $m(Z) = 0.1382 - \frac{0.3211}{Z^2}$, $C(Z) = 0.1904 - 0.2235 \ln Z + 0.1292 (\ln Z)^2 - 0.01491 (\ln Z)^3$, where $Z$ is the average charge of an atomic nucleus. As a result, the following values were obtained: $\eta(\text{As}_2\text{Se}_{96}) \approx 0.29$ (for sapphire, $\eta(\text{Al}_2\text{O}_3) = 0.037$). The coefficient of secondary emission $\delta$ does not depend monotonically on $Z$ [18]. For the $\text{As}_2\text{Se}_{96}$ film, $Z$ is 33.96 and, according to [18], we took $\delta \approx 0.3$ and $Q_+ = 2.3$ pC, subsequently. The use of a low-pressure nitrogen in a SEM chamber also supplements the formation of a positive charge on the film surface.

The average depth of the yield of secondary electrons for the $\text{As}_2\text{Se}_{96}$ film was calculated by the formula [19]:

$$\lambda = \frac{0.267 A_0 I}{\rho Z^{\frac{4}{3}}} [\text{mm}],$$

(4)

where $A_0$ is the atomic weight, $Z$ is the ordinal number, $\rho$ is the matter density, and $I$ is the first ionization potential (9.56 eV for $\text{As}_2\text{Se}_{96}$ [20]). The depth of the yield of secondary electrons for the $\text{As}_2\text{Se}_{96}$ film is $\lambda = 4.4$ mm. The depth of the output of reflected electrons $X_\eta$ is determined by the empirical formula [21]:

$$x_\eta = R 0.45 e^{-0.22(I+1)}.$$

(5)

For the $\text{As}_2\text{Se}_{96}$ film with $x_\eta = 1.3$ μm, a layer of negative charge appears in the film due to the inelastic scattering of primary electrons in the interaction region, and their capture by deep centers and various defects. The total negative charge $Q_- = (1 - \eta) I_0 t$, which is formed in the film depth, is determined by the total irradiation time. It also depends on changes in $\eta$ during the irradiation due to the presence of a surface (positive or negative) potential $V$. The changes of $\eta(t)$ for the $\text{As}_2\text{Se}_{96}$ film are not known. For $\eta(t) = \text{const} = 0.41$, $t = 0.5$ with $Q_- = 12.3$ nC.

It is seen from Fig. 2 that the area of the axial section of the surface cones $S$ increases linearly to $t = 1$ ms. It can be assumed that, at $t = 1$ ms, the positive charge maximally spreads over the surface in the irradiation region. The increase in $d(t)$ at $t > 1$ ms indicates a further increase in the charge accumulated region. At $t > 50$ ms, $d(t) \approx \text{const} = 8.1$ μm. This value is comparable to the value of the interaction region $R \approx 6.3$ μm for the $\text{As}_2\text{Se}_{96}$ film. We can assume that, with the chosen parameters of the electron irradiation, the time of the formation of a SCR in this film is 50 ms. A higher value of $d > R$ in this case may be due to the partial diffusion of charges from the interaction region into the depth of the film by an amount $\Delta R$. Proceeding from the obtained numerical values of the parameters of the interaction of the film with the electron beam, it is possible to represent the charge model for the $\text{As}_2\text{Se}_{96}$ film (Fig. 3) [6].

4.1. Electronic lithography on $\text{As}_2\text{Se}_{96}$ film

The appearance of a surface relief of various shapes on an $\text{As}_2\text{Se}_{96}$ film under the electron irradiation indicates a possibility of using this material as an elec-
of the surface relief that forms the image data was about the diameter of the electron beam (\(g_i\)) and inverse (\(g_1\)) radiation doses, as well as the parameters of the charge model for the investigated film, are determined. The possibility of using this film for the single-stage electron lithography is shown. Images of some logoses that can be used to make protective holograms are made on the surface of the As\(_4\)Se\(_96\) film.

5. Conclusions

Three intervals of radiation doses of the As\(_4\)Se\(_96\) film in which the processes of charge accumulation and redistribution occur in the region of its interaction with the electron beam are determined. The threshold (\(G_0\)) and inverse (\(G_1\)) radiation doses, as well as the parameters of the charge model for the investigated film, are determined. The possibility of using this film for the single-stage electron lithography is shown. Images of some logoses that can be used to make protective holograms are made on the surface of the As\(_4\)Se\(_96\) film.
