The Daya Bay Reactor Neutrino Experiment was designed to measure $\theta_{13}$, the smallest mixing angle in the three-neutrino mixing framework, with unprecedented precision. The experiment consists of eight identically designed detectors placed underground at different baselines from three pairs of nuclear reactors in South China. Since Dec. 2011, the experiment has been running stably for more than 7 years, and has collected the largest reactor antineutrino sample to date. Daya Bay greatly improved the precision on $\theta_{13}$ and made an independent measurement of the effective mass splitting in the electron antineutrino disappearance channel. Daya Bay also performed a number of other precise measurements such as a high-statistics determination of the absolute reactor antineutrino flux and the spectrum evolution, as well as a search for the sterile neutrino mixing, among others. The most recent results from Daya Bay are discussed in this paper, as well as the current status and future prospects of the experiment.

Keywords: neutrino oscillation, neutrino mixing, reactor, Daya Bay.

1. Daya Bay Neutrino Experiment

The Daya Bay Reactor Neutrino Experiment was designed to measure $\theta_{13}$, the smallest mixing angle in the three-neutrino mixing framework, with unprecedented precision [1]. The experiment profits from a rare constellation of a nuclear power station complex situated near Hong Kong and adjacent mountains. The reactors serve as the source of neutrinos, while the mountains provide a sufficient overburden suppressing cosmic muons – the strongest background source (see Fig. 1). The Daya Bay and Ling Ao nuclear power plant (NPP) reactors (red circles) were situated on a narrow coastal shelf between the Daya Bay coastline and inland mountains.

At the time of the measurement, the facility consisted of six pressurized water reactors (PWRs). The electron antineutrinos are emitted in the beta-decay of fission fragments released in the chain reaction. The antineutrino flux and the energy spectrum is determined by the total thermal power of the reactor, the fraction of each fissile isotope in the fuel, the fission rate of each isotope, and the energy spectrum of neutrinos from each isotope. All the reactors have the same thermal power $2.9\text{ GW}_\text{th}$ each and all together produced roughly $3.5 \times 10^{21}\bar{\nu}_e$/s with energies up to 8 MeV making it one of the most intense $\bar{\nu}_e$ sources on the Earth.

Two antineutrino detectors installed in each underground experimental hall near to the reactors (Hall 1 and Hall 2) measured the $\bar{\nu}_e$ flux emitted by the reactors, while four detectors in the far experimental hall (Hall 3) measured a deficit in the $\bar{\nu}_e$ flux due to oscillations in the location, where the neutrino oscillation effect is expected to be the strongest. Such configuration allows one to suppress the reactor-related uncertainty in the measured neutrino flux. The disappearance signal is most pronounced at the first oscillation minimum. Based on the existing accelerator and atmospheric neutrino oscillation measurements, this corresponded to the distance $L_f \approx 1.6$ km for the reactor $\bar{\nu}_e$ with a mean energy of 4 MeV. The detectors were built and initially tested in a surface assembly building (SAB), transported to a liquid scintillator hall for the filling, and then installed in an experimental hall.

The detection of antineutrinos is based on the same principle as in the famous experiment of Reines and Cowan [2], who registered reactor antineutrinos in 1956. A sensitive part of the detector consists of a hydrogen-rich liquid scintillator doped with gadolinium (Reines and Cowan used Cd instead as the dopant). Antineutrino interacts via the inverse...
beta-decay (IBD)
\[ \bar{\nu}_e + p \rightarrow e^+ + n \]

with a proton (hydrogen) giving rise to a neutron and a positron. The positron deposits its kinetic energy to the scintillator, then annihilates on an electron, and generates two gamma rays, each 511 keV which together with the deposited positron kinetic energy cause a "prompt signal" within a few nanoseconds. The neutron is first moderated and then is captured on Gd typically 30 ns after the prompt signal. Consequently, a cascade of gamma quanta with a total energy of 8 MeV is emitted and generates a "delayed signal". The appearance of the two signals "prompt" and "delayed" is a signature of the antineutrino registration.

The Daya Bay antineutrino detector modules have an onion-like structure (see Fig. 2, left). The innermost volume is filled with 20 tons of the Gd-loaded liquid scintillator (GdLS) serving as the antineutrino target. The second layer – the gamma catcher – is filled with additional 20 tons of a normal liquid scintillator (LS) which can register most of the gamma energies from the neutron capture or positron annihilation. Neutrino interactions in the gamma catcher will not satisfy the trigger, since only the signal of the neutron-capture on Gd will trigger a neutrino event. The outer-most layer is normal mineral oil (MO) that shields the radiation from the PMT glass from entering the fiducial volume. The two inner vessels are fabricated of PMMA which is transparent for optical photons and chemically resistant against the used liquids, the outer-most 5 m by 5 m tank is made of a stainless steel and is equipped with 192 8-inch PMTs. Specular reflectors are located above and below the outer PMMA vessel to improve the light collection uniformity, while the vertical wall of the detector is black. Three automated calibration units are used to deploy radioactive sources ($^{60}$Co, $^{68}$Ge, and $^{241}$Am-$^{13}$C) and light-emitting diodes through narrow teflon-bellow penetrations into the GdLS and LS regions.

After the filling, the antineutrino detectors were installed in a 10 m deep water pool in each underground experimental hall, as shown in Fig. 2, right. The water shielded the detectors from $\gamma$-rays arising from the natural radioactivity and muon-induced neutrons, which were primarily emanated from the cavern rock walls. The pool was optically separated into two independent regions, the inner (IWS) and outer water shields (OWS). Both regions were instrumented with PMTs to detect the Cherenkov light produced by cosmogenic muons. A 4-layer resistive plate chamber (RPC) system was installed over the pool, which served in studies of muons and muon-induced backgrounds. The identification of muons which passed through the IWS, OWS, and RPC system enhanced the rejection of the background from neutrons generated by muon interactions in the immediate vicinity of the antineutrino detectors. Each detector (ADs, IWS, OWS) operated as an independently triggered system.

2. Results

2.1. Oscillation analysis based on n-Gd [3]

The presented results are from the analysis of data collected in the Daya Bay experiment with 6 detectors in 217 days (Dec/2011–Jul/2012), with 8 detectors in 1524 days (Oct/2012–Dec/2016), and with 7 detectors in 217 days (Jan/2017–Aug/2017). During 1958 days of operation, the Daya Bay experiment collected more than 3.5 millions inverse beta decays in the near halls and more than 0.5 million IBD have been detected in the far hall. The daily rate is \( \sim 2500 \) IBD events in the near halls and \( \sim 300 \) IBD in the far hall.

The distortion of the energy spectrum at the far hall relative to near halls was consistent with oscillations and allowed the measurement of \( |\Delta m^2_{e\mu}| \). The
parameters of the three-flavor model in the best agreement with the observed rate and energy spectra were

\[
\sin^2 2\theta_{13} = 0.0856 \pm 0.0029,
\]

\[
|\Delta m^2_{ee}| = [2.522^{+0.068}_{-0.070}] \times 10^{-3} \text{ eV}^2,
\]

\[
\Delta m^2_{32}(NH) = +[2.471^{+0.068}_{-0.070}] \times 10^{-3} \text{ eV}^2,
\]

\[
\Delta m^2_{32}(IH) = -[2.575^{+0.068}_{-0.070}] \times 10^{-3} \text{ eV}^2.
\]

The \(\Delta m^2_{32}\) values were obtained under the assumptions of normal (NH) and inverted (IH) mass orderings.

Figure 3 – left, shows the observed electron survival probability as a function of the effective baseline \(L_{\text{eff}}\) divided by the average antineutrino energy \(\langle E_\nu\rangle\). Almost one full oscillation disappearance and reappearance cycle was sampled, given the range of \(L/E_\nu\) values which were measured.

The confidence intervals for \(\Delta m^2_{ee}\) versus \(\sin^2 2\theta_{13}\) are shown in Fig. 3 – right. The 1\(\sigma\), 2\(\sigma\), and 3\(\sigma\) 2-D confidence intervals are estimated using \(\Delta \chi^2\) values of 2.30 (red), 6.18 (green), and 11.83 (blue) relative to the best fit. The upper panel provides the 1-D \(\Delta \chi^2\) for \(\sin^2 2\theta_{13}\) obtained by profiling \(|\Delta m^2_{ee}|\) (blue line), and the dash lines mark the corresponding 1\(\sigma\), 2\(\sigma\),

The Daya Bay results are compatible with the sin^2 2θ_{13} results provided by other experiments: RENO [4], D-Chooz [5], T2K [6], MINOS [8], NOvA [9], Super-K [10], and IceCube [11]. While the accuracy of determination of |Δm_{32}^2| is comparable with T2K and MINOS, the determination of sin^2 2θ_{13} is more than twice more accurate than other results.

### 2.2. Oscillation analysis based on n-H [12]

The alternative analysis of data taken in 621 days and based on the events in which the neutron from IBD is captured in hydrogen results in

\[ \sin^2 2\theta_{13} = 0.071 \pm 0.011. \]

The combination of the n-H and n-Gd results from 1230 days data gives the 8% improvement in precision:

\[ \sin^2 2\theta_{13} = 0.082 \pm 0.004. \]

### 2.3. Search for Light Sterile Neutrino

The large statistics collected with the full configuration of eight detectors in the Daya Bay experiment allowed a new precise analysis with aim to search for a light sterile neutrino [13]. A relative comparison of the rate and energy spectrum of reactor antineutrinos in the three experimental halls yields no evidence of the sterile neutrino mixing in the 2 × 10^{-4} < |Δm_{41}^2| < 0.3 eV^2 mass range. The resulting limits on sin^2 2θ_{14} shown in Fig. 4 – left, constitute the most stringent constraints to date in the |Δm_{41}^2| < 0.2 eV^2 region.

Searches for a light sterile neutrino have been independently performed by the MINOS and Daya Bay experiments using the muon (anti)neutrino and electron antineutrino disappearance channels, respectively. Results from both experiments are combined with those from the Bugey-3 reactor neutrino experiment to constrain oscillations into light sterile neutrinos [14]. The three experiments are sensitive to complementary regions of the parameter space, enabling the combined analysis to probe the regions allowed by the LSND and MiniBooNE experiments in a minimally extended four-neutrino flavor framework. Stringent limits on sin^2 2θ_{μe} are set over six orders of magnitude in the sterile mass-squared splitting |Δm_{31}^2|. The sterile-neutrino mixing phase space allowed by the LSND and MiniBooNE experiments is excluded for |Δm_{31}^2| < 0.8 eV^2 at 95% CLs, see Fig. 4 – right.

### 2.4. Reactor antineutrino flux and spectrum anomalies [15]

Data collected in 1230 days were used to measure the IBD yield in four near detectors. The new av-
Fig. 5. Ratio of the measured antineutrino yield to the Huber–Vogel theoretical prediction vs. the distance from detector to detector – left. Comparison of the predicted and measured prompt energy spectra – right.

Fig. 6. Combined measurement of $^{235}$U and $^{239}$Pu IBD yields per fission $\sigma_{235}$ and $\sigma_{239}$ – left. Decomposition of the reactor anti-neutrino spectrum into two dominant contributions from $^{235}$U and $^{239}$Pu.

erage IBD yield is determined to be $(5.91 \pm 0.09) \times 10^{-43}$ cm$^2$/fission, and the updated ratio of measured to predicted flux was found to be $0.952 \pm 0.014 \pm 0.023$ and $1.001 \pm 0.015 \pm 0.027$ for the Huber+Mueller and ILL+Vogel models, respectively, where the first and second uncertainties are experimental and theoretical model uncertainties, respectively. The tension with respect to the theoretical predictions is consistent with other experiments, see Fig. 5 – left. In particular, an excess of events in the region of 4–6 MeV was found in the measured spectrum, with a local significance of 4.4$\sigma$, see Fig. 5 – right.

2.5. Evolution of the reactor antineutrino flux and spectrum [16]

The data taken by the detectors in two near halls in 1230 days spanning multiple fuel cycles for each of the reactors were used for the investigation of the evolution of the antineutrino flux and spectrum. Weakly effective fission fractions values corresponding to the fission isotopes $^{235}$U, $^{238}$U, $^{239}$Pu, and $^{241}$Pu for each
detector were calculated using thermal power and fission fraction data for each core, which were provided by the power plant.

A decrease of the total IBD yield/fission with increase of the effective fission fraction $F_{239}$ of $^{239}$Pu (larger fuel burn-up) was clearly observed. Individual yields $\sigma_{235}$ and $\sigma_{239}$ from the main flux contributors $^{235}$U and $^{239}$Pu, respectively, were fitted, see Fig. 6 – left. The discrepancy in a variation of the antineutrino flux from $^{235}$U with respect to the reactor fuel composition model prediction suggests a 7.8% overestimation of the predicted antineutrino flux from $^{235}$U and indicates that this isotope could be the primary contributor to the reactor antineutrino anomaly.

2.6. Reactor antineutrino spectrum decomposition [17]

The analysis of 3.5 millions of events taken during 1958 days in four near antineutrino detectors allows the partial decomposition of the antineutrino spectra – see Fig. 6 – right. The IBD yields and prompt energy spectra of $^{235}$U and $^{239}$Pu are obtained using the evolution of the prompt spectrum as a function of the fission fractions. The analysis confirms the discrepancy between the measured spectrum shape and the prediction. The deviation is 5.3$\sigma$ and 6.3$\sigma$ in the energy interval 0.7–8 MeV and in a local energy interval of 4–6 MeV, respectively.

The comparison of the measured and predicted $^{235}$U and $^{239}$Pu IBD yields prefers an incorrect prediction of the $^{235}$U flux as the primary source of the reactor antineutrino rate anomaly. The discrepancy in the spectral shape for $^{235}$U suggests the incorrect spectral shape prediction for the $^{235}$U spectrum. However, no such conclusion can be drawn for the $^{239}$Pu spectrum due to a larger uncertainty.

НОВІТНІ РЕЗУЛЬТАТИ
З ЕКСПЕРИМЕНТУ НЕЙТРИННИХ
ОСЦИЛЯЦІЙ DAYA BAY

Резюме

Експеримент з реакторних нейтрино DAYA BAY задумано для вимірювання \( \Theta_{13} \) – найменшого кута в рамках тринейтринового змішування – з безпрецедентною точністю. Експериментальна система складається з восьми однакових детекторів, розміщених від землі на різних базових відстанях від трьох пар ядерних реакторів Південного Китаю. Починаючи від 2011 року, експериментальна система працює стабільно впродовж більш ніж 7 років та накопичила найбільше як на сьогодні даних про реакторні антинейтрино. DAYA BAY значно покращив точність \( \Theta_{13} \) і виконав незалежні вимірювання ефективного розщеплення мас в каналі зникнення електронного нейтрино. DAYA BAY провів також інші точні експерименти, такі як вимірювання з високою точністю абсолютного потоку реакторних нейтрино і їхнього спектра, а також пошук змішування стерильних нейтрино. В даній роботі обговорюються новітні результати з DAYA BAY, а також сучасний стан та перспективи експерименту.
